Semi-Amortized Variational Autoencoders

Yoon Kim ¹ Sam Wiseman ¹ Andrew C. Miller ¹ David Sontag ² Alexander M. Rush ¹

Abstract
Amortized variational inference (AVI) replaces instance-specific local inference with a global inference network. While AVI has enabled efficient training of deep generative models such as variational autoencoders (VAEs), recent empirical work suggests that inference networks can produce suboptimal variational parameters. We propose a hybrid approach, to use AVI to initialize the variational parameters and run stochastic variational inference (SVI) to refine them. Crucially, the local SVI procedure is itself differentiable, so the inference network and generative model can be trained end-to-end with gradient-based optimization. This semi-amortized approach enables the use of rich generative models without experiencing the posterior-collapse phenomenon common in training VAEs for problems like text generation. Experiments show this approach outperforms strong autoregressive and variational baselines on standard text and image datasets.

1. Introduction
Variational inference (VI) (Jordan et al., 1999; Wainwright & Jordan, 2008) is a framework for approximating an intractable distribution by optimizing over a family of tractable surrogates. Traditional VI algorithms iterate over the observed data and update the variational parameters with closed-form coordinate ascent updates that exploit conditional conjugacy (Ghahramani & Beal, 2001). This style of optimization is challenging to extend to large datasets and non-conjugate models. However, recent advances in stochastic (Hoffman et al., 2013), black-box (Ranganath et al., 2014; 2016), and amortized (Mnih & Gregor, 2014; Kingma & Welling, 2014; Rezende et al., 2014) variational inference have made it possible to scale to large datasets and rich, non-conjugate models (see Blei et al. (2017), Zhang et al. (2017) for a review of modern methods).

In stochastic variational inference (SVI), the variational parameters for each data point are randomly initialized and then optimized to maximize the evidence lower bound (ELBO) with, for example, gradient ascent. These updates are based on a subset of the data, making it possible to scale the approach. In amortized variational inference (AVI), the local variational parameters are instead predicted by an inference (or recognition) network, which is shared (i.e. amortized) across the dataset. Variational autoencoders (VAEs) are deep generative models that utilize AVI for inference and jointly train the generative model alongside the inference network.

SVI gives good local (i.e. instance-specific) distributions within the variational family but requires performing optimization for each data point. AVI has fast inference, but having the variational parameters be a parametric function of the input may be too strict of a restriction. As a secondary effect this may militate against learning a good generative model since its parameters may be updated based on suboptimal variational parameters. Cremer et al. (2018) observe that the amortization gap (the gap between the log-likelihood and the ELBO due to amortization) can be significant for VAEs, especially on complex datasets.

Recent work has targeted this amortization gap by combining amortized inference with iterative refinement during training (Hjelm et al., 2016; Krishnan et al., 2018). These methods use an encoder to initialize the local variational parameters, and then subsequently run an iterative procedure to refine them. To train with this hybrid approach, they utilize a separate training time objective. For example Hjelm et al. (2016) train the inference network to minimize the KL-divergence between the initial and the final variational distributions, while Krishnan et al. (2018) train the inference network with the usual ELBO objective based on the initial variational distribution.

In this work, we address the train/test objective mismatch and consider methods for training semi-amortized variational autoencoders (SA-VAEs) in a fully end-to-end manner. We propose an approach that leverages differentiable optimization (Domke, 2012; Maclaurin et al., 2015; Belanger et al., 2017) and differentiates through SVI while training the inference network/generative model. We find that this method is able to both improve estimation of variational parameters and produce better generative models.

¹School of Engineering and Applied Sciences, Harvard University, Cambridge, MA, USA ²CSAIL & IMES, Massachusetts Institute of Technology, Cambridge, MA, USA. Correspondence to: Yoon Kim <yoonkim@seas.harvard.edu>.

We apply our approach to train deep generative models of text and images, and observe that they outperform autoregressive/VAE/SVI baselines, in addition to direct baselines that combine VAE with SVI but do not perform end-to-end training. We also find that under our framework, we are able to utilize a powerful generative model without experiencing the “posterior-collapse” phenomenon often observed in VAEs, wherein the variational posterior collapses to the prior and the generative model ignores the latent variable (Bowman et al., 2016; Chen et al., 2017; Zhao et al., 2017). This problem has particularly made it very difficult to utilize VAEs for text, an important open issue in the field. With SA-VAE, we are able to outperform an LSTM language model by utilizing an LSTM generative model that maintains non-trivial latent representations. Code is available at https://github.com/harvardnlp/sa-vaes.

2. Background

Notation Let \( f : \mathbb{R}^n \rightarrow \mathbb{R} \) be a scalar valued function with partitioned inputs \( u = [u_1, \ldots, u_m] \) such that \( \sum_{i=1}^m \text{dim}(u_i) = n \). With a slight abuse of notation we define \( f(u_1, \ldots, u_m) = f([u_1, \ldots, u_m]) \). We denote \( \nabla_u f(\hat{u}) \in \mathbb{R}^{\text{dim}(u)} \) to be the i-th block of the gradient of \( f \) evaluated at \( \hat{u} = [\hat{u}_1, \ldots, \hat{u}_m] \), and further use \( \frac{df}{dv} \) to denote the total derivative of \( f \) with respect to \( v \), which exists if \( u \) is a differentiable function of \( v \). Note that in general \( \nabla_u f(\hat{u}) \neq \frac{df}{du} \) since other components of \( u \) could be a function of \( u_1 \). We also let \( H_{u_1, u_2} f(\hat{u}) \in \mathbb{R}^{\text{dim}(u_1) \times \text{dim}(u_2)} \) be the matrix formed by taking the i-th group of rows and the j-th group of columns of the Hessian of \( f \) evaluated at \( \hat{u} \). These definitions generalize straightforwardly when \( f : \mathbb{R}^n \rightarrow \mathbb{R}^p \) is a vector-valued function (e.g. \( \frac{df}{dv} \in \mathbb{R}^{n \times p} \)).

2.1. Variational Inference

Consider the following generative process for \( x \),
\[
\mathbf{z} \sim p(\mathbf{z}) \quad x \sim p(x | \mathbf{z}; \theta)
\]
where \( p(\mathbf{z}) \) is the prior and \( p(x | \mathbf{z}; \theta) \) is given by a generative model with parameters \( \theta \). As maximizing the log-likelihood \( \log p(x; \theta) = \log \int p(x | \mathbf{z}; \theta)p(\mathbf{z})d\mathbf{z} \) is usually intractable, variational inference instead defines a variational family of distributions \( q(\mathbf{z} | \lambda) \) parameterized by \( \lambda \) and maximizes the evidence lower bound (ELBO)
\[
\log p(x; \theta) \geq \mathbb{E}_{q(\mathbf{z} | \lambda)}[\log p(x | \mathbf{z}; \theta)] - \text{KL}[q(\mathbf{z} | \lambda) || p(\mathbf{z})] = \text{ELBO}(\lambda, \theta, x)
\]
The variational posterior, \( q(\mathbf{z} | \lambda) \), is said to collapse to the prior if \( \text{KL}[q(\mathbf{z} | \lambda) || p(\mathbf{z})] \approx 0 \). In the general case we are given a dataset \( x^{(1)}, \ldots, x^{(N)} \) and need to find variational parameters \( \lambda^{(1)}, \ldots, \lambda^{(N)} \) and generative model parameters \( \theta \) that jointly maximize \( \sum_{i=1}^N \text{ELBO}(\lambda^{(i)}, \theta, x^{(i)}) \).

2.2. Stochastic Variational Inference

We can apply SVI (Hoffman et al., 2013) with gradient ascent to approximately maximize the above objective:

1. Sample \( x \sim p(x) \)
2. Randomly initialize \( \lambda_0 \)
3. For \( k = 0, \ldots, K-1 \), set \( \lambda_{k+1} = \lambda_k + \alpha \nabla_\lambda \text{ELBO}(\lambda_k, \theta, x) \)
4. Update \( \theta \) based on \( \nabla_\theta \text{ELBO}(\lambda_K, \theta, x) \)

Here \( K \) is the number of SVI iterations and \( \alpha \) is the learning rate. (Note that \( \theta \) is updated based on the gradient \( \nabla_\theta \text{ELBO}(\lambda_k, \theta, x) \) and not the total derivative \( \frac{d \text{ELBO}(\lambda_k, \theta, x)}{d \theta} \). The latter would take into account the fact that \( \lambda_k \) is a function of \( \theta \) for \( k > 0 \).)

SVI optimizes directly for instance-specific variational distributions, but may require running iterative inference for a large number of steps. Further, because of this block coordinate ascent approach the variational parameters \( \lambda \) are optimized separately from \( \theta \), potentially making it difficult for \( \theta \) to adapt to local optima.

2.3. Amortized Variational Inference

AVI uses a global parametric model to predict the local variational parameters for each data point. A particularly popular application of AVI is in training the variational autoencoder (VAE) (Kingma & Welling, 2014), which runs an inference network (i.e. encoder) \( \text{enc}(\cdot) \) parameterized by \( \phi \) over the input to obtain the variational parameters:

1. Sample \( x \sim p(x) \)
2. Set \( \lambda = \text{enc}(x; \phi) \)
3. Update \( \theta \) based on \( \nabla_\theta \text{ELBO}(\lambda, \theta, x) \) (which in this case is equal to the total derivative)
4. Update \( \phi \) based on
\[
\frac{d \text{ELBO}(\lambda, \theta, x)}{d \phi} = \frac{d \lambda}{d \phi} \nabla_\lambda \text{ELBO}(\lambda, \theta, x)
\]
The inference network is learned jointly alongside the generative model with the same loss function, allowing the pair to coadapt. Additionally inference for AVI involves running the inference network over the input, which is usually much faster than running iterative optimization on the ELBO. Despite these benefits, requiring the variational parameters to be a parametric function of the input may be too strict of a

---

1This will indeed be the case in our approach: when we calculate ELBO(\( \lambda_K, \theta, x \)), \( \lambda_K \) is a function of the data point \( x \), the generative model \( \theta \), and the inference network \( \phi \) (Section 3).

2While we describe the various algorithms for a specific data point, in practice we use mini-batches.
Semi-Amortized Variational Autoencoders

3. Semi-Amortized Variational Autoencoders

Semi-amortized variational autoencoders (SA-VAE) utilize an inference network over the input to give the initial variational parameters, and subsequently run SVI to refine them. One might appeal to the universal approximation theorem (Hornik et al., 1989) and question the necessity of additional momentum on the negative ELBO, is shown in Algorithm 1.

SA-VAE models are trained using a combination of AVI and SVI steps:

1. Sample \( x \sim p_D(x) \)
2. Set \( \lambda_0 = \text{enc}(x; \phi) \)
3. For \( k = 0, \ldots, K - 1 \), set
   \[
   \lambda_{k+1} = \lambda_k + \alpha \nabla_{\lambda} \text{ELBO}(\lambda_k, \theta, x)
   \]
4. Update \( \theta \) based on
   \[
   \frac{d \text{ELBO}(\lambda_k, \theta, x)}{d \theta}
   \]
5. Update \( \phi \) based on
   \[
   \frac{d \text{ELBO}(\lambda_k, \theta, x)}{d \phi}
   \]

Note that for training we need to compute the total derivative of the final ELBO with respect to \( \theta, \phi \) (i.e., steps 4 and 5 above). Unlike with AVI, in order to update the encoder and generative model parameters, this total derivative requires backpropagating through the SVI updates. Specifically this requires backpropagating through gradient ascent (Domke, 2012; Maclaurin et al., 2015).

Following past work, this backpropagation step can be done efficiently with fast Hessian-vector products (LeCun et al., 1993; Pearlmutter, 1994). In particular, consider the case where we perform one step of refinement, \( \lambda_1 = \lambda_0 + \alpha \nabla_{\lambda} \text{ELBO}(\lambda_0, \theta, x) \), and for brevity let \( L = \text{ELBO}(\lambda_1, \theta, x) \). To backpropagate through this, we receive the derivative \( \frac{dL}{d\lambda_0} \) and use the chain rule,

\[
\frac{dL}{d\lambda_0} = \frac{d\lambda_1}{d\lambda_0} \frac{dL}{d\lambda_1} = (1 + \alpha H_{\lambda, \lambda} \text{ELBO}(\lambda_0, \theta, x)) \frac{dL}{d\lambda_1}
\]

\[
= \frac{dL}{d\lambda_1} + \alpha H_{\lambda, \lambda} \text{ELBO}(\lambda_0, \theta, x) \frac{dL}{d\lambda_1}
\]

We can then backpropagate \( \frac{dL}{d\lambda_0} \) through the inference network to calculate the total derivative, i.e., \( \frac{dL}{d\phi} = \frac{d\lambda_0}{d\phi} \frac{dL}{d\lambda_0} \).

Similar rules can be used to derive \( \frac{dL}{d\theta} \). The full forward/backward step, which uses gradient descent with momentum on the negative ELBO, is shown in Algorithm 1.

**Algorithm 1 Semi-Amortized Variational Autoencoders**

**Input:** inference network \( \phi \), generative model \( \theta \), inference steps \( K \), learning rate \( \alpha \), momentum \( \gamma \), loss function \( f(\lambda, \theta, x) = -\text{ELBO}(\lambda, \theta, x) \)

Sample \( x \sim p_D(x) \)

\[
\lambda_0 = \text{enc}(x; \phi)
\]

\[
v_0 = 0
\]

**for** \( k = 0 \) **to** \( K - 1 \) **do**

\[
v_{k+1} = \gamma v_k - \nabla_{\lambda} f(\lambda_k, \theta, x)
\]

\[
\lambda_{k+1} = \lambda_k + \alpha v_{k+1}
\]

**end for**

\[
L = f(\lambda_K, \theta, x)
\]

\[
\lambda_K = \nabla_{\lambda} f(\lambda_K, \theta, x)
\]

\[
\theta = \theta - H_{\theta, \lambda} f(\lambda_k, \theta, x) \nabla_{\lambda} \theta
\]

\[
v_K = \gamma v_{K+1}
\]

**for** \( k = K - 1 \) **to** \( 0 \) **do**

\[
v_k = \gamma v_{k+1} + \alpha \lambda_{k+1}
\]

\[
\lambda_k = \lambda_k + H_{\lambda, \lambda} f(\lambda_k, \theta, x) \nabla_{\lambda} \theta
\]

**end for**

\[
\frac{\partial L}{\partial \phi} = \theta
\]

\[
\frac{\partial L}{\partial \theta} = \frac{\partial \lambda_0}{\partial \theta} \frac{\partial L}{\partial \lambda_0}
\]

Update \( \theta, \phi \) based on \( \frac{\partial L}{\partial \theta}, \frac{\partial L}{\partial \phi} \)

In our implementation we calculate Hessian-vector products with finite differences (LeCun et al., 1993; Domke, 2012), which was found to be more memory-efficient than automatic differentiation (and therefore crucial for scaling our approach to rich inference networks/generative models).

Specifically, we estimate \( H_{u_i, u_j} f(\hat{u}) v \) with

\[
H_{u_i, u_j} f(\hat{u}) v \approx \frac{1}{\epsilon} \left( \nabla_{u_i} f(\hat{u}_0, \ldots, \hat{u}_j + \epsilon v, \ldots, \hat{u}_m) - \nabla_{u_i} f(\hat{u}_0, \ldots, \hat{u}_j, \ldots, \hat{u}_m) \right)
\]

where \( \epsilon \) is some small number (we use \( \epsilon = 10^{-5} \)).

We further clip the results (i.e., rescale the results if the norm exceeds a threshold) before and after each Hessian-vector product as well as during SVI, which helped mitigate exploding gradients and further gave better training signal to the inference network. See Appendix A for details.

---

4We refer the reader to Domke (2012) for the full derivation.

5Since in our case the ELBO is a non-deterministic function due to sampling (and dropout, if applicable), care must be taken when calculating Hessian-vector product with finite differences to ensure that the source of randomness is the same when calculating the two gradient expressions.

6Without gradient clipping, in addition to numerical issues we empirically observed the model to degenerate to a case whereby it learned to rely too much on iterative inference, and thus the initial parameters from the inference network were poor. Another way to provide better signal to the inference network is to train against a weighted sum \( \sum_{k=0}^{K} w_k \text{ELBO}(\lambda_k, \theta, x) \) for \( w_k \geq 0 \).
4. Experiments

We apply our approach to train generative models on a synthetic dataset in addition to text/images. For all experiments we utilize stochastic gradient descent with momentum on the negative ELBO. Our prior is the spherical Gaussian \( \mathcal{N}(0, I) \) and the variational posterior is diagonal Gaussian, where we set the variational parameters according to the following oracle generative process with \( \theta \):

\[
\begin{align*}
    z_1, z_2 &\sim \mathcal{N}(0, 1) \\
    h_t &= \text{LSTM}(h_{t-1}, x_t) \\
    x_{t+1} &\sim \text{softmax}(\text{MLP}(h_t, z_1, z_2))
\end{align*}
\]

We initialize the LSTM/MLP randomly as \( \theta \), and the variational parameters are given by the mean vector and the diagonal log variance vector, i.e. \( \lambda = [\mu, \log \sigma^2] \).

In preliminary experiments we also experimented with natural gradients, other optimization algorithms, and learning the learning rates, but found that these did not significantly improve results. Full details regarding hyperparameters/model architectures for all experiments are in Appendix B.

4.1. Synthetic Data

We first apply our approach to a synthetic dataset where we have access to the true underlying generative model of discrete sequences. We generate synthetic sequential data according to the following oracle generative process with 2-dimensional latent variables and \( x_t \):

\[
\begin{align*}
    z_1, z_2 &\sim \mathcal{N}(0, 1) \\
    h_t &= \text{LSTM}(h_{t-1}, x_t) \\
    x_{t+1} &\sim \text{softmax}(\text{MLP}(h_t, z_1, z_2))
\end{align*}
\]

We initialize the LSTM/MLP randomly as \( \theta \), where the LSTM has a single layer with hidden state/input dimension equal to 100. We generate for 5 time steps (so each example is given by \( x = [x_1, \ldots, x_5] \)) with a vocabulary size of 1000 for each \( x_t \). Training set consists of 5000 points. See Appendix B.1 for the exact setup.

We fix this oracle generative model \( p(x \mid z; \theta) \) and learn an inference network (also a one-layer LSTM) with VAE and SA-VAE.\(^7\) For a randomly selected test point, we plot the ELBO landscape in Figure 1 as a function of the variational posterior means \( \mu_1, \mu_2 \) for a randomly chosen test point. Variational parameters obtained from VAE, SVI are shown as \( \mu_{\text{VAE}}, \mu_{\text{SVI}} \) and the initial/final parameters from SA-VAE are shown as \( \mu_0 \) and \( \mu_K \) (along with the intermediate points). SVI/SA-VAE are run for 20 iterations. The optimal point, found from grid search, is shown as \( \mu^* \).

![Image](image.png)

**Figure 1.** ELBO landscape with the oracle generative model as a function of the variational posterior means \( \mu_1, \mu_2 \) for a randomly chosen test point. Variational parameters obtained from VAE, SVI are shown as \( \mu_{\text{VAE}}, \mu_{\text{SVI}} \) and the initial/final parameters from SA-VAE are shown as \( \mu_0 \) and \( \mu_K \) (along with the intermediate points). SVI/SA-VAE are run for 20 iterations. The optimal point, found from grid search, is shown as \( \mu^* \).

**Table 1.** Variational upper bounds for the various models on the synthetic dataset, where SVI/SA-VAE is trained/tested with 20 steps. **True NLL (Est)** is an estimate of the true negative log-likelihood (i.e. entropy of the data-generating distribution) estimated with 1000 samples from the prior. **Oracle Gen** uses the oracle generative model and **Learned Gen** learns the generative network.

ELBO landscape escape.

As can be seen from Figure 1, the variational parameters from running SA-VAE are closest to the optimum while those obtained from SVI and VAE are slightly further away. In Table 1 we show the variational upper bounds (i.e. negative ELBO) on the negative log-likelihood (NLL) from training the various models with both the oracle/learned generative model, and find that SA-VAE outperforms VAE/SVI in both cases.

4.2. Text

The next set of experiments is focused on text modeling on the Yahoo questions corpus from Yang et al. (2017). Text modeling with deep generative models has been a challenging problem, and few approaches have been shown to produce rich generative models that do not collapse to standard language models. Ideally a deep generative model trained with variational inference would make use of the latent space (i.e. maintain a nonzero KL term) while accurately modeling the underlying distribution.

Our architecture and hyperparameters are identical to the LSTM-VAE baselines considered in Yang et al. (2017), except that we train with SGD instead of Adam, which was found to perform better for training LSTMs. Specifically, both the inference network and the generative model are one-layer LSTMs with 1024 hidden units and 512-dimensional word embeddings. The last hidden state of the encoder is used to predict the vector of variational posterior means/log variances. The sample from the variational posterior is used to predict the initial hidden state of the generative LSTM and additionally fed as input at each time step. The latent variable is 32-dimensional. Following previous works (Bowman et al., 2016; Sønderby et al., 2016; Yang et al., 2017), for all the variational models we utilize a KL-cost annealing strategy whereby the multiplier on the KL term is increased linearly from 0.1 to 1.0 each batch over 10 epochs. Appendix B.2 has the full architecture/hyperparameters.

\(^7\)With a fixed oracle, these models are technically not VAEs as VAE usually implies that the generative model is learned (alongside the encoder).
### Table 2. Results on text modeling on the Yahoo dataset. Top results are from Yang et al. (2017), while the bottom results are from this work (+ INIT means the encoder is initialized with a pretrained language model, while models with + WORD-DROP are trained with word-dropout). NLL/KL numbers are averaged across examples, and PPL refers to perplexity. $K$ refers to the number of inference steps used for training/testing.

### Figure 2. (Left) Perplexity upper bound of various models when trained with 20 steps (except for VAE) and tested with varying number of SVI steps from random initialization. (Right) Same as the left except that SVI is initialized with variational parameters obtained from the inference network.

Models trained with word dropout (+ WORD-DROP in Table 2) do make use of the latent space but significantly underperform a language model. In contrast, models that combine amortized inference with iterative refinement make use of the latent space and the KL term is significantly above zero. VAE + SVI and VAE + SVI + KL do not outperform a language model, while SA-VAE only modestly outperforms it, to our knowledge this is one of the first instances in which we are able to train an LSTM generative model that does not ignore the latent code and outperforms a language model.

One might wonder if the improvements are coming from simply having a more flexible inference scheme at test time, rather than from learning a better generative model. To test this, for the various models we discard the inference network at test time and perform SVI for a variable number of steps from random initialization. The results are shown in Figure 2 (left). It is clear that the learned generative model (and the associated ELBO landscape) is quite different—it is not possible to train with VAE and perform SVI at test time to obtain the same performance as SA-VAE (although the performance of VAE does improve slightly from 62.7 to 62.3 when we run SVI for 40 steps from random initialization).

Figure 2 (right) has the results for a similar experiment where we refine the variational parameters initialized from the inference network for a variable number of steps at test time. We find that the inference network provides better initial parameters than random initialization and thus requires fewer iterations of SVI to reach the optimum. We do not observe improvements for running more refinement steps than was used in training at test time. Interestingly, SA-VAE without any refinement steps at test time has a substantially nonzero KL term ($KL = 6.65$, $PPL = 62.0$). This indicates that the posterior-collapse phenomenon when...

Table 3. Results on image modeling on the OMNIGLOT dataset. Top results are from prior works, while the bottom results are from this work. GATED PIXELCNN is our autoregressive baseline, and $K$ refers to the number of inference steps during training/testing. For the variational models the KL portion of the ELBO is shown in parentheses.

4.3. Images

We next apply our approach to model images on the OMNIGLOT dataset (Lake et al., 2015). While posterior collapse is less of an issue for VAEs trained on images, we still expect that improving the amortization gap would result in generative models that better model the underlying data and make more use of the latent space. We use a three-layer ResNet (He et al., 2016) as our inference network. The generative model first transforms the 32-dimensional latent vector to the image spatial resolution, which is concatenated with the original image and fed to a 12-layer Gated PixelCNN (van den Oord et al., 2016) with varying filter sizes, followed by a final sigmoid layer. We employ the same KL-cost annealing schedule as in the text experiments. See Appendix B.3 for the exact architecture/hyperparameters.

Results from the various models are shown in Table 3. Our findings are largely consistent with results from text: the semi-amortized approaches outperform VAE/SVI baselines, and further they learn generative models that make more use of the latent representations (i.e. KL portion of the loss is higher). Even with 80 steps of SVI we are unable to perform as well as SA-VAE trained with 10 refinement steps, indicating the importance of good initial parameters provided by the inference network. In Appendix C we further investigate the performance of VAE and SA-VAE as we vary the training set size and the capacity of the inference network/generative model. We find that SA-VAE outperforms VAE and has higher latent variable usage in all scenarios. We note that we do not outperform the state-of-the-art models that employ hierarchical latent variables and/or more sophisticated priors (Chen et al., 2017; Tomczak & Welling, 2018). However these additions are largely orthogonal to our approach and we hypothesize they will also benefit from combining amortized inference with iterative refinement.11

5. Discussion

5.1. Learned Latent Space

For the text model we investigate what the latent variables are learning through saliency analysis with our best model (SA-VAE trained with 20 steps). Specifically, we calculate the output saliency of each token $x_t$ with respect to $z$ as

$$
E_{q(z;\lambda)} \left[ \left\| \frac{\partial \log p(x_t | x_{<t}; z; \theta)}{\partial z} \right\|_2 \right]
$$

where $\| \cdot \|_2$ is the $l_2$ norm and the expectation is approximated with 5 samples from the variational posterior. Saliency is therefore a measure of how much the latent variable is being used to predict a particular token.

We visualize the saliency of a few examples from the test set in Figure 3 (top). Each example consists of a question followed by an answer from the Yahoo corpus. From a qualitative analysis several things are apparent: the latent variable seems to encode question type (i.e. if, what, how, why, etc.) and therefore saliency is high for the first word; content words (nouns, adjectives, lexical verbs) have much higher saliency than function words (determiners, prepositions, conjunctions, etc.); saliency of the $<$/s> token is quite high, indicating that the length information is also encoded in the latent space. In the third example we observe that the left parenthesis has higher saliency than the right parenthesis (0.32 vs. 0.24 on average across the test set), as the latter can be predicted by conditioning on the former rather than on the latent representation $z$.

The previous definition of saliency measures the influence of $z$ on the output $x_t$. We can also roughly measure the influence of the input $x_t$ on the latent representation $z$, which we refer to as input saliency:

$$
\left\| \frac{\partial E_{q(z;\lambda)} \left[ \|z\|_2 \right]}{\partial w_t} \right\|_2
$$

11Indeed, Cremer et al. (2018) observe that the amortization gap can be substantial for VAE trained with richer variational families.
Here $w_t$ is the encoder word embedding for $x_t$. We visualize the input saliency for a test example (Figure 3, middle) and a made-up example (Figure 3, bottom). Under each input example we also visualize two samples from the variational posterior, and find that the generated examples are often meaningfully related to the input example.

We quantitatively analyze output saliency across part-of-speech, token position, word frequency, and log-likelihood in Figure 4: nouns (NN), adjectives (JJ), verbs (VB), numbers (CD), and the </s> token have higher saliency than conjunctions (CC), determiners (DT), prepositions (IN), and the TO token—the latter are relatively easier to predict by conditioning on previous tokens; similarly, on average, tokens occurring later have much higher saliency than those occurring earlier (Figure 4 shows absolute position but the plot is similar with relative position); the latent variable is used much more when predicting rare tokens; there is some negative correlation between saliency and log-likelihood (-0.51), though this relationship does not always hold—e.g. </s> has high saliency but is relatively easy to predict with an average log-likelihood of -1.61 (vs. average log-likelihood of -4.10 for all tokens). Appendix D has the corresponding analysis for input saliency, which are qualitatively similar.

These results seem to suggest that the latent variables are encoding interesting and potentially interpretable aspects of language. While left as future work, it is possible that manipulations in the latent space of a model learned this way could lead to controlled generation/manipulation of output text (Hu et al., 2017; Mueller et al., 2017).

5.2. Limitations

A drawback of our approach (and other non-amortized inference methods) is that each training step requires backpropagating through the generative model multiple times, which can be costly especially if the generative model is expensive to compute (e.g. LSTM/PixelCNN). This may potentially be mitigated through more sophisticated meta learning ap-
proaches (Andrychowicz et al., 2016; Marino et al., 2018), or with more efficient use of the past gradient information during SVI via averaging (Schmidt et al., 2013) or importance sampling (Sakaya & Klami, 2017). One could also consider employing synthetic gradients (Jaderberg et al., 2017) to limit the number of backpropagation steps during training. Krishnan et al. (2018) observe that it is more important to train with iterative refinement during earlier stages (we also observed this in preliminary experiments), and therefore annealing the number of refinement steps as training progresses could also speed up training.

Our approach is mainly applicable to variational families that avail themselves to differentiable optimization (e.g. gradient ascent) with respect to the ELBO, which include much recent work on employing more flexible variational families with VAEs. In contrast, VAE + SVI and VAE + SVI + KL are applicable to more general optimization algorithms.

6. Related Work

Our work is most closely related the line of work which uses a separate model to initialize variational parameters and subsequently updates them through an iterative procedure (Salakhutdinov & Larochelle, 2010; Cho et al., 2013; Salimans et al., 2015; Hjelm et al., 2016; Krishnan et al., 2018; Pu et al., 2017). Marino et al. (2018) utilize meta-learning to train an inference network which learns to perform iterative inference by training a deep model to output the variational parameters for each time step.

While differentiating through inference/optimization was initially explored by various researchers primarily outside the area of deep learning (Stoyanov et al., 2011; Domke, 2012; Brakel et al., 2013), they have more recently been explored in the context of hyperparameter optimization (Maclaurin et al., 2015) and as a differentiable layer of a deep model (Belanger et al., 2017; Kim et al., 2017; Metz et al., 2017; Amos & Kolter, 2017).

Initial work on VAE-based approaches to image modeling focused on simple generative models that assumed independence among pixels conditioned on the latent variable (Kingma & Welling, 2014; Rezende et al., 2014). More recent works have obtained substantial improvements in log-likelihood and sample quality through utilizing powerful autoregressive models (PixelCNN) as the generative model (Chen et al., 2017; Gulrajani et al., 2017). In contrast, modeling text with VAEs has remained challenging. Bowman et al. (2016) found that using an LSTM generative model resulted in a degenerate case whereby the variational posterior collapsed to the prior and the generative model ignored the latent code (even with richer variational families). Many works on VAEs for text have thus made simplifying conditional independence assumptions (Miao et al., 2016; 2017), used less powerful generative models such as convolutional networks (Yang et al., 2017; Semeniuta et al., 2017), or combined a recurrent generative model with a topic model (Dieng et al., 2017; Wang et al., 2018). Note that unlike to sequential VAEs that employ different latent variables at each time step (Chung et al., 2015; Fraccaro et al., 2016; Krishnan et al., 2017; Serban et al., 2017; Goyal et al., 2017a), in this work we focus on modeling the entire sequence with a global latent variable.

Finally, since our work only addresses the amortization gap (the gap between the log-likelihood and the ELBO due to amortization) and not the approximation gap (due to the choice of a particular variational family) (Cremer et al., 2018), it can be combined with existing work on employing richer posterior/prior distributions within the VAE framework (Rezende & Mohamed, 2015; Kingma et al., 2016; Johnson et al., 2016; Tran et al., 2016; Goyal et al., 2017b; Guu et al., 2017; Tomczak & Welling, 2018).

7. Conclusion

This work outlines semi-amortized variational autoencoders, which combine amortized inference with local iterative refinement to train deep generative models of text and images. With the approach we find that we are able to train deep latent variable models of text with an expressive autoregressive generative model that does not ignore the latent code.

From the perspective of learning latent representations, one might question the prudence of using an autoregressive model that fully conditions on its entire history (as opposed to assuming some conditional independence) given that \( p(x) \) can always be factorized as \( \prod_{t=1}^{T} p(x_t | x_{<t}) \), and therefore the model is non-identifiable (i.e. it does not have to utilize the latent variable). However in finite data regimes we might still expect a model that makes use of its latent variable to generalize better due to potentially better inductive bias (from the latent variable). Training generative models that both model the underlying data well and learn good latent representations is an important avenue for future work.

Supplementary Materials for Semi-Amortized Variational Autoencoders

A. Training Semi-Amortized Variational Autoencoders with Gradient Clipping

For stable training we found it crucial to modify Algorithm 1 to clip the gradients at various stages. This is shown in Algorithm 2, where we have a clipping parameter \( \eta \). The clip(\( \cdot \)) function is given by

\[
\text{clip}(u, \eta) = \begin{cases} \frac{\eta}{\|u\|_2} u & \text{if } \|u\|_2 > \eta \\ u & \text{otherwise} \end{cases}
\]

We use \( \eta = 5 \) in all experiments. The finite difference estimation itself also uses gradient clipping. See https://github.com/harvardnlp/sa-vae/blob/master/optim_n2n.py for the exact implementation.

B. Experimental Details

For all the variational models we use a spherical Gaussian prior. The variational family is the diagonal Gaussian parameterized by the vector of means and log variances. For models trained with SVI the initial variational parameters are randomly initialized from a Gaussian with standard deviation equal to 0.1.

B.1. Synthetic Data

We generate synthetic data points according to the following generative process:

\[
\begin{align*}
z_1, z_2 &\sim \mathcal{N}(0, 1) \\
h_t &= \text{LSTM}(h_{t-1}, x_t) \\
x_{t+1} &\sim \text{softmax} (\text{MLP}([h_t, z_1, z_2]))
\end{align*}
\]

Here LSTM is a one-layer LSTM with 100 hidden units where the input embedding is also 100-dimensional. The initial hidden/cell states are set to zero, and we generate for 5 time steps for each example (so \( x = [x_1, \ldots, x_5] \)). The MLP consists of a single affine transformation to project out to the vocabulary space, which has 1000 tokens. LSTM/MLP parameters are randomly initialized with \( \mathcal{U}(-1, 1) \), except for the part of the MLP that directly connects to the latent variables, which is initialized with \( \mathcal{U}(-5, 5) \). This is done to make sure that the latent variables have more influence in predicting \( x \). We generate 5000 training/validation/test examples.

When we learn the generative model the LSTM is initialized over \( \mathcal{U}(-0.1, 0.1) \). The inference network is also a one-layer LSTM with 100-dimensional hidden units/input embeddings, where the variational parameters are predicted via an affine transformation on the final hidden state of the encoder. All models are trained with stochastic gradient descent with batch size 50, learning rate 1.0, and gradient clipping at 5. The learning rate starts decaying by a factor of 2 each epoch after the first epoch at which validation performance does not improve. This learning rate decay is not triggered for the first 5 epochs. We train for 20 epochs, which was enough for convergence of all models. For SVI/SA-VAE we perform 20 steps of iterative inference with stochastic gradient descent and learning rate 1.0 with gradient clipping at 5.

B.2. Text

We use the same model architecture as was used in Yang et al. (2017). The inference network and the generative model are both one-layer LSTMs with 1024-dimensional
Table 4. Upper bounds on negative log-likelihood (i.e. negative ELBO) of VAE/SA-VAE trained on OMNIGLOT, where we vary the capacity of the inference network (3-layer ResNet vs 2-layer MLP). KL portion of the loss is shown in parentheses. (Top) Here we vary the training set size from 25% to 100%, and use a 12-layer PixelCNN as the generative model. (Bottom) Here we fix the training set size to be 100%, and vary the capacity of the generative model.

The preprocessed OMNIGLOT dataset does not have a standard validation split so we randomly pick 2000 images from training as validation. As with previous works the pixel value is scaled to be between 0 and 1 and interpreted as probabilities, and the images are dynamically binarized during training.

Our inference network consists of 3 residual blocks where each block is made up of a standard residual layer (i.e. two convolutional layers with $3 \times 3$ filters, ReLU nonlinearities, batch normalization, and residual connections) followed by a downsampling convolutional layer with filter size and stride equal to 2. These layers have 64 feature maps. The output of residual network is flattened and then used to obtain the variational means/log variances via an affine transformation.

The sample from the variational distribution (which is 32-dimensional) is first projected out to the image spatial resolution with 4 feature maps (i.e. $4 \times 28 \times 28$) via a linear transformation, then concatenated with the original image, and finally fed as input to a 12-layer Gated PixelCNN (van den Oord et al., 2016). The PixelCNN has three $9 \times 9$ layers, followed by three $7 \times 7$ layers, then three $5 \times 5$ layers, and finally three $3 \times 3$ layers. All the layers have 32 feature maps, and there is a final $1 \times 1$ convolutional layer followed by a sigmoid nonlinearity to produce a distribution over binary output. The layers are appropriately masked to ensure that the distribution over each pixel is conditioned only on the pixels left/top of it. We train with Adam with learning rate 0.001, $\beta_1 = 0.9$, $\beta_2 = 0.999$ for 100 epochs with batch size of 50. Gradients are clipped at 5.

For models trained with iterative inference we perform SVI via stochastic gradient descent with momentum 0.5 and learning rate 1.0, with gradient clipping (also at 5).

### B.3. Images

The preprocessed OMNIGLOT dataset does not have a standard validation split so we randomly pick 2000 images from training as validation. As with previous works the pixel value is scaled to be between 0 and 1 and interpreted as probabilities, and the images are dynamically binarized during training.

Our inference network consists of 3 residual blocks where each block is made up of a standard residual layer (i.e. two convolutional layers with $3 \times 3$ filters, ReLU nonlinearities, batch normalization, and residual connections) followed by a downsampling convolutional layer with filter size and stride equal to 2. These layers have 64 feature maps. The output of residual network is flattened and then used to obtain the variational means/log variances via an affine transformation.

The sample from the variational distribution (which is 32-dimensional) is first projected out to the image spatial resolution with 4 feature maps (i.e. $4 \times 28 \times 28$) via a linear transformation, then concatenated with the original image, and finally fed as input to a 12-layer Gated PixelCNN (van den Oord et al., 2016). The PixelCNN has three $9 \times 9$ layers, followed by three $7 \times 7$ layers, then three $5 \times 5$ layers, and finally three $3 \times 3$ layers. All the layers have 32 feature maps, and there is a final $1 \times 1$ convolutional layer followed by a sigmoid nonlinearity to produce a distribution over binary output. The layers are appropriately masked to ensure that the distribution over each pixel is conditioned only on the pixels left/top of it. We train with Adam with learning rate 0.001, $\beta_1 = 0.9$, $\beta_2 = 0.999$ for 100 epochs with batch size of 50. Gradients are clipped at 5.

For models trained with iterative inference we perform SVI via stochastic gradient descent with momentum 0.5 and learning rate 1.0, with gradient clipping (also at 5).

### C. Data Size/Model Capacity

In Table 4 we investigate the performance of VAE/SA-VAE as we vary the capacity of the inference network, size of the training set, and the capacity of the generative model. The MLP inference network has two ReLU layers with 128 hidden units. For varying the PixelCNN generative model,
Semi-Amortized Variational Autoencoders

Figure 5. Input saliency by part-of-speech tag (left), position (center), and log frequency (right). The dotted gray line in each plot shows the average saliency across all words.

we sequentially remove layers from our baseline 12-layer model starting from the bottom (so the 9-layer PixelCNN has three $7 \times 7$ layers, three $5 \times 5$ layers, three $3 \times 3$ layers, all with 32 feature maps).

Intuitively, we expect iterative inference to help more when the inference network and the generative model are less powerful, and we indeed see this in Table 4. Further, one might expect SA-VAE to be more helpful in small-data regimes as it is harder for the inference network amortize inference and generalize well to unseen data. However we find that SA-VAE outperforms VAE by a similar margin across all training set sizes.

Finally, we observe that across all scenarios the KL portion of the loss is much higher for models trained with SA-VAE, indicating that these models are learning generative models that make more use of the latent representations.

D. Input Saliency Analysis

In Figure 5 we show the input saliency by part-of-speech tag (left), position (center), and frequency (right). Input saliency of a token $x_t$ is defined as:

$$
\left\| \mathbb{E}_{q(z|x)} \left[ \frac{d\|z\|_2}{dW_t} \right] \right\|_2
$$

Here $w_t$ is the encoder word embedding for $x_t$. Part-of-speech tagging is done using NLTK.
